## Abstract

*Due to its high protocol overhead, both in data traffic and in round-trips, Java RMI is poorly suited for communication over slow wireless links. However, its performance can be enhanced without breaking compatibility with Java RMI specification, and with minimal changes to existing software and network hosts. This paper analyzes the reasons for the poor performance of Java RMI, outlines a solution based on mediator technology and evaluates the performance of a prototype implementing the solution.*

## 1. Introduction

Remote Method Invocation (RMI) [20] is the object-oriented version of the well-known Remote Procedure Call [7]. RMI is essentially the same concept that allows the programmer to transparently invoke methods on objects that reside on another computer. In this way, the object-oriented paradigm is preserved in distributed computing. There are several implementation architectures for the remote method invocation. The most well-known one is CORBA [23], which has several commercial implementations available. However, with the success of the Java language, Java RMI is earning more and more attention. In contrast to CORBA that is programming language independent, Java RMI only works between Java programs. On the other hand, Java RMI is far more flexible than CORBA. Jini Connection Technology [2] and most Agent Platforms use Java RMI as a communication framework. The importance of Java RMI also increases due to the announcements of many mobile terminal device manufacturers that their equipment will support Java in the future.

Current and forthcoming wireless data services—GSM

Data Service, GPRS, UMTS, wireless LAN—enrich the options for communications. Unfortunately, the current Internet-based solutions are not able to fulfill all the needs of nomadic users [21]. The environment of mobile computing is very different compared to today's environment of traditional distributed systems in many respects. Bandwidth, latency, delay, error rate and interference, among other things, may change dramatically as a nomadic end-user moves from one location to another—from an environment to another: from a wired LAN via a wireless LAN to a GPRS/UMTS network for example.

Today the Internet offers a communication backbone to an ever-increasing amount of information services. In fact some persons (not necessarily addicted but primarily due to their profession) have become increasingly dependent on access to those services. By using wireless networks, those persons can utilize network information services even when they are on the move. However, current communication services do not work well in a mobile environment because applications and middleware products, on which the applications run, were designed for fixed, reliable networks. The problems are due to manifold reasons; including sudden loss of connectivity, low bandwidth, high latency, and high cost of wireless communication. Many of the problems can be solved by using light-weight, mobile-aware protocols and middleware in the wireless environment.

Given that Java RMI is gaining popularity, it is only a matter of time before the performance of Java RMI over wireless links becomes important. We have analyzed and measured performance characteristics of Java RMI over GSM Data Service and High Speed Data Service [10]. We examined two platforms—Linux and Windows NT—and several variations of a commercially available GSM HSCSD. The results are not encouraging: Java RMI works poorly in slow wireless environments. This is due to the well-known poor performance of TCP in a wireless environment but also due to the Java RMI protocol itself.

In this paper we propose a mediator-based solution to overcome those problems. Mediators—known as *performance enhancing proxies* in IETF [8]—are widely used to improve TCP/IP performance on communication paths including a slow wireless link. Examples include Indirect TCP by Rutgers University [3], Snoop by the University of California at Berkeley [5], Mowgli by the University of Helsinki [16], and TACO by the University of Copenhagen [12]. Mediators are also used to improve application level protocols like HTTP [17, 28]. In addition, the WAP architecture [30] is also based on mediators.

In a mediator-based solution there are *access nodes* in the fixed network that serve the mobile terminals by providing them with an access point to the fixed network. Each application, that is not mobile aware, requires two mediators: An *agent*, which is located in the mobile terminal, is bound with the terminal part of the application (usually a client), and a *proxy*, which is located at the access node, is bound to the fixed network part of the application (usually a server).

All communication between the terminal and the fixed network part of the application goes via the agent and proxy, which collaborate to optimize the communication over the wireless link.

The rest of this paper is organized as follows. In Section 2 we give background information on how Java RMI works, and why it works poorly in slow wireless environments. In Section 3 we present our approach to optimizing Java RMI, using a solution based on mediator technology. In Section 4 we evaluate the performance of our approach. We briefly summarize related work in Section 5. Finally, Section 6 states the conclusions.

## 2. Background and Motivation

### 2.1. Java RMI Protocol

Java RMI was designed to simplify the communication between two objects in different virtual machines by allowing transparent calls to methods in remote virtual machines. Once a reference of a remote object is obtained, it is possible to call methods of that object in the same way as methods of local objects. Since the remote object resides in a different virtual machine, an RMI *Registry* is needed to manage remote references. When an RMI server wants to make its local methods available to remote objects, it registers the objects to a local registry. A remote object connects to the remote registry, which listens to a well-known socket, and obtains a remote reference.

Java RMI is built on top of a *transport layer*, which provides abstract RMI connections built on top of TCP connections. When an RMI connection is opened, the transport

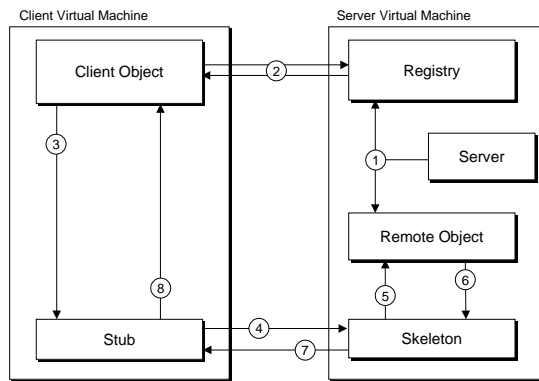

Figure 1. Java RMI Protocol

layer either opens a new TCP connection, or reuses an existing one if a free one is available. If the reused connection has been idle for more than the time of a round-trip, the transport layer first sends a ping packet to make sure the connection is still working. Once an acknowledgment for the ping packet is received, the new RMI connection is established. If a TCP connection has not been used by any RMI connections for a while, it is closed.

The general Java RMI architecture is depicted in Figure 1. First a server creates a remote object and registers it to a local Registry (1). The client then connects to the remote Registry (2) and obtains the remote reference. At this point, a stub of the remote object is transferred from the remote virtual machine to the client virtual machine, if the stub is not yet present. When the client (3) invokes a method at a remote object, the method is actually invoked at the local stub. The stub marshals the parameters and sends a message (4) to the associated skeleton on the server side. The skeleton unmarshals the parameters and invokes the appropriate method (5). The remote object executes the method and passes the return value back to the skeleton (6), which marshals it and sends a message to the associated stub on the client side (7). Finally the stub unmarshals the return value and passes it to the client (8).

### 2.2. RMI Problems

#### 2.2.1. RMI Use of TCP Connections

The reuse of TCP connections in the transport layer is commendable because it saves resources. However, the implementation causes frequent ping messages. This is problematic with high-round-trip wireless connections.

While Java RMI is not optimal for wireless networks, neither is TCP upon which Java RMI is built. The problems with TCP in a wireless environment are well-known [16, 9]. Especially in JDK1.1, RMI and TCP conspire to produce bad results. RMI writes header data byte by byte, and because of the slow start algorithm [14], TCP has to wait

**Figure 2. The trace of the “sayHello” remote invocation**

for an acknowledgment once it has sent the first segment containing only one byte. This means that it takes a full round-trip before the second segment can be sent.

In JDK1.2 (Java<sup>TM</sup> 2), data is no longer written byte by byte, and the performance is much better. However, the protocol itself still enforces many round-trips for a single invocation (due mainly to the ping packets).

### 2.2.2. Analysis of an RMI Call

In this section we will show an analysis of a simple RMI call. The method is called “sayHello”. As return value the method returns the String “Hello World”.

In our test the stub class was already present on the client side, so there was no need to download the stub class. The trace of the call is outlined below (see Figure 2):

1. The first round-trip is between the client and the Registry on the remote side and uses a new TCP connection (TCP1). The registry returns an acknowledgment of the RMI protocol and what it believes to be the client’s IP address (EPId). It should be noted that this first round-trip happens every time a new connection is opened.
2. In the second round-trip, the client requests (and obtains) the remote reference of the desired remote class.

At this point, the RMI connection is closed, logically closing the TCP1 connection.

3. Opening a second TCP connection TCP2, the client connects with the server. Since this is the first RMI call a header and a protocol acknowledgment are exchanged.
4. The client-side Distributed Garbage Collection (DGC) requests from the server a lease of the required remote reference through a *Dirty()* invocation. The RMI connection is closed, logically closing the TCP2 connection.
5. At this point, the Client must tell the DGC of the Registry that it obtained a remote reference, so it opens a new RMI connection. The first round-trip between the client and the Registry is a ping: in this way the client verifies that the TCP connection, which was logically closed before, is still alive<sup>1</sup>. Having verified this, the client communicates to the Registry that it has received a lease from the server with a DGCAck message.<sup>2</sup>
6. In parallel with the previous point, the client can invoke the remote method on the server. But, since the RMI connection was closed, a ping round-trip takes place. After this, the client invokes the method and obtains the results of the invocation as return value.
7. When the client does not need the remote reference any more, usually when the remote reference is locally unreferenced, it sends a “clean” message to the server. This exchange is preceded by the usual ping round-trip.

Data traffic is summarized in Table 1. In each row is given the amount of data (and percentages) transferred in each transfer pattern.

On a slow wireless link the amount of data that is sent over the link is important. In this example, the actual invocation takes up only 5% of the total transmitted data while 69% was related to the DGC protocol. This means that the channel is primarily used for auxiliary data, making the invocation expensive.

Another important issue is the high number of round-trips. On slow links, like GSM, even a single byte exchange like ping causes delays due to the long latency times involved (a round-trip over GSM is typically around one second). In this example, six round-trips were necessary before the invocation was completed, not counting the two round-trips caused by TCP handshaking. However, only two are

<sup>1</sup>Note that a ping does not occur if the TCP connection has been idle for a time less than a ping round-trip.

<sup>2</sup>Before this acknowledgment has been sent, the Registry must not release its server reference, since that might cause the server to wrongly conclude that there are no references in use.

**Table 1. Invocation data traffic (bytes)**

	Client to Server and Registry	Server and Registry to Client	Total
Registry Lookup	55 (6%)	276 (42%)	331 (20%)
Invocation Data	41 (4%)	37 (6%)	78 (5%)
DGC Data	831 (85%)	305 (46%)	1136 (69%)
Protocol Overhead	52 (5%)	40 (6%)	92 (6%)
Total	979 (100%)	658 (100%)	1637 (100%)

really needed - one to get the server reference, and another for the actual invocation.

### 3. The Monads Approach

#### 3.1. Optimizations

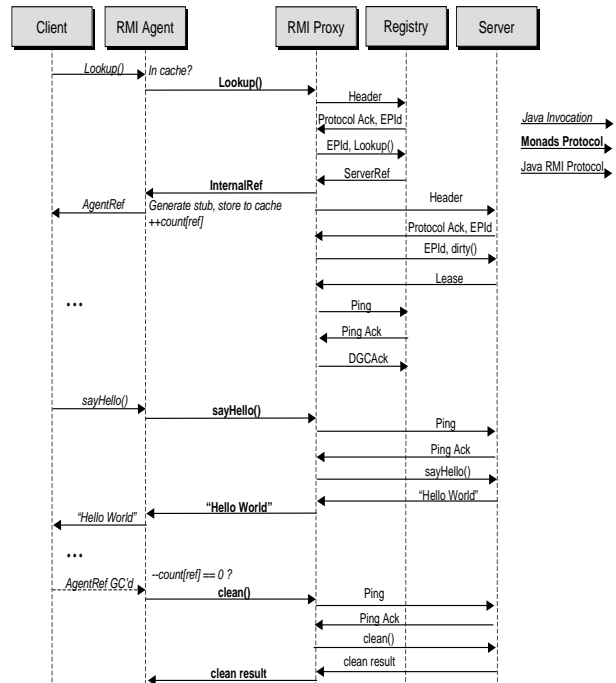

Optimization of Java RMI for wireless links means a reduction of protocol overhead and the number of round-trips. We have two ways to reach this goal: The first one is to change the implementation itself, i.e. to change JDK system classes. The disadvantage is that modification of both client and server host software is necessary, and that makes this solution unattractive. The second solution, presented here, attempts to preserve the original implementation supporting it with the use of mediators and compression to avoid, where possible, every redundant communication between the client side and the server side<sup>3</sup>. The solution uses a mediator architecture, with an RMI agent in the mobile terminal and an RMI proxy in the fixed network. The proposed optimizations are outlined below.

**Data compression** – The serialization protocol used by Java RMI produces a large amount of overhead in the invocation. Since we do not want to modify the source code, the easiest way to reduce this overhead is to compress the data using a generic compression algorithm. In our prototype we use the GZIP standard file format.

**Protocol Acknowledgment** – The acknowledgments are handled by the RMI proxy, and do not cross the wireless link.

**Registry lookups** – When a client does a lookup for the first time, the remote reference is cached locally, and the original reference in the Registry is marked as cached by the mediator on the other side. Mediators

<sup>3</sup>Note that RMI is used symmetrically—a mobile terminal may have both RMI clients and servers. This symmetry must be preserved.

**Figure 3. Using mediators to optimize the remote invocation**

synchronize cached references by notifying their peer when a reference marked as cached changes. To reduce initial cache misses, the reference cache can be initialized with frequently used references at startup.

**Distributed Garbage Collection** – This protocol introduces heavy data overhead and its use in a wireless environment is less meaningful, since the link is subject to sudden disconnections that can be handled at the transport layer. To avoid its redundancy and high number of round-trips, the client and the server can be decoupled. The use of mediators for this decoupling is explained in the next section.

#### 3.2. Use of Mediators

The role of the RMI mediators is shown in Figure 3. The RMI Agent captures the invocation made by the client. A lookup request is first checked in the local cache, and only if the remote reference is unknown is the request forwarded to the server.

DGC invocations are optimized by decoupling client and server. The RMI proxy keeps servers alive by periodically renewing the leases. It will only stop doing so once the RMI agent tells it that no more references to the server exist on the other side. In this way the DGC semantics are loosened to suit the needs of wireless communication, without

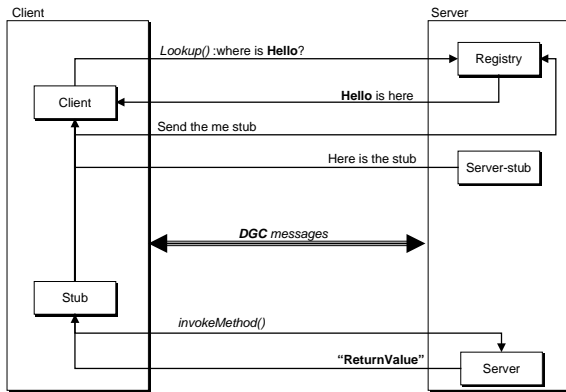

Figure 4. The normal RMI structure

Figure 5. Optimized RMI structure

modifying client or server code. No lease requests (*dirty()* invocations) need to be sent over the wireless link, since all leases are managed on the fixed network side. In this way the number of round-trips is minimized. The amount of data transferred over the wireless link is also reduced. Of course, clean requests still have to be sent to inform the other side that no references to a server exist anylonger. An optimized data representation can be used for these requests, further reducing DGC overhead. The Figures 4 and 5 outline the difference between our RMI optimization and the normal RMI.

## 4. Performance Evaluation

The performance of our optimized RMI implementation was measured in field trials. The objective was to study how our system behaves in different circumstances and to compare its performance with regular RMI.

### 4.1. Test Arrangements

In the measurements, we used a configuration specified in Table 2. The mobile node was connected to the Access Node using GSM HSCSD data service. Technically

Table 2. Hardware used in the measurements

Mobile Terminal	Toshiba Portégé 7020CT (Intel Pentium II/366MHz; 128Mb Main Memory)
Access Node	Compaq DeskPro EN6350 (Intel Pentium II/400MHz; 128Mb Main Memory)
GSM Phone	Nokia CardPhone 2.0 (Prototype)
Access Node Modem	Multitech MT2834ZDXI (28.8Kbps)

the HSCSD consists of two parts: multislot capability and the modified channel-coding scheme. The former provides the use of several parallel time slots per user where normal GSM can use only one. At the beginning of the HSCSD service, the maximum number of time slots is mostly limited to 3+1 (asymmetrical connection, three time slots for downlink) and 2+2 (symmetrical connection). The modified channel-coding scheme provides the user with a data rate of 14.4 kbps instead of the original maximum 9.6 kbps. In order to achieve higher bit rates, a more efficient puncturing method is used. This, on the other hand, decreases the radio interface error-correction performance. Therefore, the 14.4 kbps channel coding cannot be used when there is a lot of noise and interference affecting the quality of the radio signal. Depending on connection type and the capabilities of the network infrastructure, the maximum user data rate can be 28.8 kbps using a modem connection, 38.4 kbps using an ISDN V.110 protocol, or 57.6 kbps using an ISDN V.120 protocol.

We performed the measurements using a modem connection, thus having 28.8 kbps as maximum user data rate. The following combinations of channel coding (CC) and time slots were used: 1+1 (96CC; original GSM), 1+1 (144CC), 2+2 (96CC), 2+2 (144CC), and 3+1 (96CC). The measurements were conducted in a normal office environment with good HSCSD radio link conditions.

The software package used in the test was the KaRMI benchmark suite provided by the Institute for Program Structures and Data Organization of the University of Karlsruhe [22]<sup>4</sup>. The test cases used are shown in Table 4. Each test was repeated 20 times in every configuration.

Since the implementation of the Java Virtual Machine and the underlying TCP/IP implementation are different in different operating systems, we conduct all the experiments in a Windows environment and in a Linux environment, as described in Table 3.

## 4.2. Summary of Performance Results

### 4.2.1. Lookup results

In the lookup case, we measured the time to get the reference to a remote object. In our optimized implementation,

<sup>4</sup>Software available at <http://www.wipd.ira.uka.de/~hauma/EfficientRMI/>

**Table 3. Test Environment**

Client		Server
Windows		
OS	Windows 98	Windows NT (SP 6)
JDK	Sun JDK 1.2.2	Sun JDK 1.2.2
Linux		
OS	Linux 2.2.14	Linux 2.2.14
JDK	Sun JDK 1.2.2	Sun JDK 1.2.2

**Table 4. Test cases set**

Name	Parameters type	Return value
Void	null	null
ReturnPing	Byte[500]	Byte[500]
PingImage	Byte[5998]	null
PingText	Byte[9689]	null
ReturnText	Byte[9689]	Byte[9689]

we did not measure the case when the reference is found in the RMI Agent's reference cache; in this case, the reference is found in a few milliseconds depending on the speed of the underlying hardware and Java implementation.

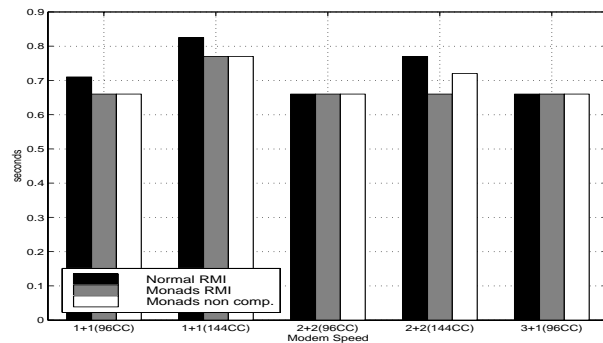

Tables 5 and 6 show the results of lookup tests in Windows and Linux respectively. As expected, our implementation is significantly faster due to the reduction of unnecessary round-trips (see Figure 6). Using the original GSM (1+1, 96CC) our implementation is more than four times faster than the normal RMI in a Windows environment, and more than five times faster in Linux. An interesting result is that in HSCSD data service using the 14.4 kbps channel-coding scheme, the round-trip time is slightly higher than using the original 9.6 kbps channel coding. Since fewer round-trips are needed in our implementation, we gain more when 14.4 kbps is used as shown in Figure 7. The actual throughput does not significantly affect lookup results, since there is only a small number of bytes to send both in our implementation and in the original Java RMI.

**Figure 6. Summary of the lookup test in a Windows environment**

**Figure 7. The difference between original RMI lookup and optimized lookup**

**Figure 8. Summary of the void ping() test in a Windows environment**

#### 4.2.2. Invocation results

In the Invocation case, we performed an extensive study using different kernels found in the KaRMI package. Table 4 summarizes the test cases we used.

First, to evaluate basic overhead caused by RMI, we used a simple remote method; with no parameters nor return value. The results are given in Tables 7 and 8 for Windows and Linux respectively. As there is only a few bytes to transfer in both directions, the difference between our implementation and original RMI is insignificant. In our implementation there is some additional processing overhead, as all invocations go through the RMI Agent. However, with the slow wireless communication path being the bottleneck, this is not a problem. In Figure 8, the results of the Windows environment are illustrated.

Next we evaluate the case where the remote object takes an array of bytes (500) as an argument, and as a return value, returns the same array back. Tables 7 and 8 summarizes the results of this test case in Windows and Linux respectively. In this case, there is now more data to send, and therefore using compression affects the results significantly. This is

mainly due to the content of the array; in the KaRMI package all arrays are always initialized with zeros.

In order to evaluate our implementation with more realistic data, we used a case where the client sends a file to the server as a parameter of a remote method, and another case, where the server also returns the same file as a return value. As the content of the file affects the results of our implementation significantly when compression is used, we selected two files with very different content; the text file used was a HTML page with size 9689 bytes and the image file used was a GIF image with size 5998 bytes. The general purpose compression algorithm we are using is not able to compress GIF images. As a result, we are not gaining anything from using compression with very random data, but on the other hand, the additional overhead needed in this case is not significant. When we are transferring text data for example, the compression works well, and our implementation is significantly faster than the original RMI. The summaries of image and text transfer results are shown in Tables 7 and 8. The results are summarized in Figure 9.

## 5. Related Work

Optimizing Java and Java RMI performance have been quite popular research topics; see for example [1]. The work, however, has concentrated on high-speed networks—to the best of our knowledge there are no published results yet on Java RMI performance in slow wireless networks (cellular networks). However, some work has been carried out for CORBA in slow wireless networks.

For the high-speed networks UKA serialization and KaRMI, developed at the University of Karlsruhe [22], provide a more efficient RMI for Java. The Manta project (Fast Parallel Java) in the Vrije Universiteit, Amsterdam [19, 29] has developed an efficient remote method invocation based on a transparent extension of Java for distributed environments. The Manta RMI is a part of the Manta environment and it cannot be used separately. At Indiana University there is a group that has conducted an interoperability and performance study of remote method invocation [6]. Another performance evaluation study has been carried out by the HORB project in Japan [13].

Wireless access and terminal mobility issues in CORBA has been studied in the EC/ACTS projects DOLMEN [18] and OnTheMove [27] as well as in the Alice project at Trinity College Dublin [11]. Somewhat related work has also been carried out in the Rover project at MIT [15]. In addition, a mobile RPC proposal, called M-RPC, has been done by Rutgers University [4].

The DOLMEN work led to OMG Telecom Domain Task Force activities: An RFI [24] was issued in June 1998, a white paper [25] in November 1998, and an RFP [26] in May 1999. The OMG specification is expected to be com-

pleted this year. It may have some implications to the Java RMI since future RMI is expected to use IIOP.

## 6. Conclusions

Due to its high protocol overhead, both in data traffic and in round-trips, Java RMI is poorly suited for wireless communication. However, it can be optimized without breaking compatibility with Java RMI specification, and with minimal changes to existing software. New software is necessary only at the mobile terminal and at its access point to the fixed network. This is possible by utilizing mediator technology, which is widely exploited in wireless communications. The results are encouraging.

In the future we will extend our implementation to support both personal and terminal mobility. These new features will greatly improve the usability of Java RMI in a mobile environment. The use of mediator technology will support the implementation of these features.

(c)

(f)

Figure 9. Figure (a) shows the invocation times of uplink image transfer using different link speeds in Linux environment. Figure (b) shows the invocation times of uplink text transfer while Figure (c) shows the invocation times of two-way text transfer in Linux environment. Figures (d),(e), and (f) show the corresponding times in the Windows environment

**Table 7. Comparison between normal RMI and optimized RMI in the Windows environment**

	Original RMI				Monads Compressed				Monads Uncompressed			
	Min	Max	Median	Average	Min	Max	Median	Average	Min	Max	Median	Average
Comparison between normal RMI and optimized RMI for the <i>Windows Void</i> case												
1+1 (96CC)	650	1380	710	719	650	720	660	662	600	880	660	651
1+1 (144CC)	760	1980	825	867	710	2040	770	835	710	2030	770	826
